Homework 3

Mengyan Jing and Abhisek Banerjee

2026-04-14

Problem 1

We have a dataset given to us as peru.txt that consists of variables possibly relating to blood pressures of n = 39 Peruvians who have moved from rural high-altitude areas to urban lower- altitude areas.

Our goal is to construct a coordinate descent algorithm to find parameter estimates for a lasso (L2) regression of systolic blood pressure on the predictors $X_1 - X_9$ (X_1 and X_9 are defined in the question).

(1) Pseudocode

We have the lasso problem

$$\min_{\boldsymbol{\beta}\in\mathbb{R}^p} \ \tfrac{1}{2}\left\|\mathbf{y} - X\boldsymbol{\beta}\right\|_2^2 \ + \ \lambda\,\|\boldsymbol{\beta}\|_1.$$

The non-smooth part $\|\boldsymbol{\beta}\|_1 = \sum_{i=1}^{p} |\beta_i|$ is separable, so coordinate descent should converge to a global minimizer. Fixing all β_j, $j \neq i$, the stationarity condition for β_i is

$$0 \ = \ X_i^\top X_i\,\beta_i \ + \ X_i^\top\big(X_{-i}\boldsymbol{\beta}_{-i} - \mathbf{y}\big) \ + \ \lambda\, s_i, \qquad s_i \in \partial|\beta_i|,$$

which is solved in closed form by soft-thresholding (from the slides of Ryan Tibshirani of Carneige Mellon University):

$$\beta_i \ \leftarrow \ S_{\lambda/\|X_i\|_2^2}\left(\frac{X_i^\top\big(\mathbf{y} - X_{-i}\boldsymbol{\beta}_{-i}\big)}{X_i^\top X_i}\right), \qquad S_\tau(z) = \operatorname{sign}(z)\big(|z| - \tau\big)_+.$$

Maintaining the full residual $\mathbf{r} = \mathbf{y} - X\boldsymbol{\beta}$, the update can be rewritten as

$$\beta_i \ \leftarrow \ S_{\lambda/\|X_i\|_2^2}\left(\frac{X_i^\top \mathbf{r}}{\|X_i\|_2^2} \ + \ \beta_i\right),$$

so each coordinate update costs $O(n)$ and one full cycle costs $O(np)$, matching the cost of one gradient-descent step. Following from the above theory, the pseudo code for our coordinate descent algorithm is as follows:

```
Inputs: Response variable  y  (in R)
        Design matrix    X  (in R^{n x p}, having columns X_1, ..., X_p)
        Penalty hyperparameter   lambda > 0
        A tolerance limit      (e.g. 1e-7)
        Number of cycles (maximum) K_max

Step 1. We can center y and each column of X (in this may the intercept will drop out)
    so... y    <- y - mean(y)
          X_i  <- X_i - mean(X_i),     i = 1, ..., p
```

```
Step 2. Compute column norms from beforehand (which is to be used in every update)
    c_i  <- ||X_i||_2^2 = X_i' X_i,   i = 1, ..., p

Step 3. Now we Initialize everything as zero
    beta <- (0, 0, ..., 0)            # p-vector of zeros
    r    <- y                         # since beta = 0
    k    <- 0

Step 4. Cyclic coordinate descent
    repeat
        beta_old <- beta
        for i = 1, 2, ..., p do
            # 1. Add coordinate i back into the residual
            r <- r + X_i * beta[i]

            # 2. Univariate OLS coefficient on the partial residual
            z_i <- (X_i' r) / c_i

            # 3. Soft-thresholding update (slide 13)
            beta[i] <- sign(z_i) * max( |z_i| - lambda / c_i , 0 )

            # 4. Subtract the new contribution back out of the residual
            r <- r - X_i * beta[i]
        end for
        k <- k + 1
    until ( max_i |beta[i] - beta_old[i]| < tol )  or  k >= K_max

Step 5. Recover the intercept on the original (uncentered) scale
    beta_0 <- mean(y_orig) - sum_i ( beta[i] * mean(X_i_orig) )

Output: (beta_0, beta_1, ..., beta_p)
```

(2) Implementation details

Starting values. All coefficients are initialized at zero ($\boldsymbol{\beta}^{(0)} = \mathbf{0}$). For lasso this is the natural choice because the L1 penalty pulls coefficients toward zero, so a zero start is consistent with the expected sparse solution.

Stopping criterion. The algorithm terminates when the maximum absolute change in any coefficient between two successive full sweeps falls below $\text{tol} = 10^{-7}$:

$$\max_i \left|\beta_i^{(k+1)} - \beta_i^{(k)}\right| < 10^{-7}.$$

We additionally enforce a hard cap of $K_{\max} = 10000$ cycles as a safety net, though convergence occurs in well under 100 cycles in practice.

Standardization. Each predictor is centered and scaled to unit standard deviation, and the response is centered. This ensures a single λ penalizes all coefficients on a comparable scale. After fitting, coefficients are converted back to the original scale and the intercept is recovered from the means.

Penalty selection. We select λ by 10-fold cross-validation using `glmnet::cv.glmnet`, then refit the coefficients with our own coordinate descent at $\lambda_{\min}$.

(3) Parameter estimates

```r
soft_threshold <- function(z, lam) sign(z) * max(abs(z) - lam, 0)

lasso_cd <- function(X, y, lambda, tol = 1e-7, max_iter = 10000) {
  n <- nrow(X); p <- ncol(X)
  X_means <- colMeans(X); X_sds <- apply(X, 2, sd)
  X_std   <- scale(X)
  y_mean  <- mean(y); y_c <- y - y_mean
  col_norm_sq <- colSums(X_std^2)
  beta <- rep(0, p)
  for (iter in 1:max_iter) {
    beta_old <- beta
    for (j in 1:p) {
      r_j <- y_c - X_std[, -j, drop = FALSE] %*% beta[-j]
      z_j <- sum(X_std[, j] * r_j) / n
      beta[j] <- soft_threshold(z_j, lambda) / (col_norm_sq[j] / n)
    }
    if (max(abs(beta - beta_old)) < tol) break
  }
  beta_orig <- beta / X_sds
  intercept <- y_mean - sum(X_means * beta_orig)
  list(intercept = intercept, beta = beta_orig, iterations = iter)
}

# Load Peru dataset (tab/space delimited, with header)
peru <- read.table("peru.txt", header = TRUE)
head(peru)
```

```
##   Age Years Weight Height Chin Forearm Calf Pulse Systol Diastol
## 1  21     1   71.0   1629  8.0     7.0 12.7    88    170      76

```

```r
# Compute the missing Fraclife variable = Years / Age
peru$Fraclife <- peru$Years / peru$Age

# Response: systolic blood pressure
y <- peru$Systol

# Predictors X1..X9 in the homework's order
X <- as.matrix(peru[, c("Age", "Years", "Fraclife", "Weight", "Height",
                        "Chin", "Forearm", "Calf", "Pulse")])
library(glmnet)
set.seed(42)
cv_fit      <- cv.glmnet(X, y, alpha = 1, nfolds = 10)
lambda_best <- cv_fit$lambda.min

fit <- lasso_cd(X, y, lambda = lambda_best)
```

```r
pred_names <- c("Age", "Years", "Fraclife", "Weight", "Height",
                "Chin", "Forearm", "Calf", "Pulse")
data.frame(
  Variable    = c("Intercept", pred_names),
  Coefficient = round(c(fit$intercept, fit$beta), 4)
)
```

```
##           Variable Coefficient
##          Intercept    133.7312
## Age            Age     -0.9047
## Years        Years      1.8569
## Fraclife  Fraclife    -92.8405
## Weight      Weight      1.4425
## Height      Height     -0.0323
## Chin          Chin     -0.9330
## Forearm    Forearm     -0.9503
## Calf          Calf     -0.0888
## Pulse        Pulse      0.0867
```

Interpretation. The lasso retains all nine predictors at the CV-selected λ, but the magnitudes reveal a clear ordering of importance. **Fraction of urban life** (-92.84) is by far the strongest predictor, indicating that individuals who spent a larger fraction of their life at lower altitude have substantially lower systolic blood pressure — consistent with cardiovascular adaptation to the altitude transition. **Weight** ($+1.44$) and **Years** in urban area ($+1.86$) enter with the expected positive signs: heavier subjects and those with longer urban exposure tend toward higher SBP. **Age** (-0.90) is modestly negative, likely reflecting the narrow age range in this sample rather than a true aging effect. The skinfold measurements (Chin, Forearm, Calf) and Pulse contribute only minor adjustments, and Height is effectively shrunk to zero (-0.03). The fact that no coefficient is driven exactly to zero suggests the CV-selected λ is relatively small, favoring predictive accuracy over aggressive sparsity on this $n = 39$ dataset.

Problem 2

Problem Setup

We estimate $\theta \geq 0$ in the density

$$f(x;\theta) = \sqrt{\tfrac{1}{4\pi}}\,\frac{\exp(-\frac{1}{4x} - \theta x)}{x^{3/2}\exp(-\sqrt{\theta})}, \qquad x > 0,$$

from 1000 test datasets, each containing $k = 50$ i.i.d. observations. This is the inverse-Gaussian family $\mathrm{IG}(\mu = \frac{1}{2\sqrt{\theta}}, \lambda = \frac{1}{2})$ for $\theta > 0$, reducing to the Lévy distribution at $\theta = 0$. Methods are scored by weighted MSE with $w(\theta) = 1/(\theta + 0.001)$, which puts enormous weight on errors near the boundary $\theta \approx 0$.

(1) Maximum Likelihood Estimation

Log-likelihood. For $\mathbf{x} = (x_1, \ldots, x_k)$,

$$\ell(\theta) = C(\mathbf{x}) - \theta \sum_{i=1}^{k} x_i + k\sqrt{\theta},$$

where $C(\mathbf{x}) = -\frac{k}{2}\log(4\pi) - \frac{3}{2}\sum \log x_i - \frac{1}{4}\sum 1/x_i$ does not depend on θ.

Optimization. Setting $\ell'(\theta) = -\sum x_i + \frac{k}{2\sqrt{\theta}} = 0$ gives the closed form

$$\hat{\theta}_{\text{MLE}} = \left(\frac{k}{2\sum x_i}\right)^2 = \frac{1}{(2\bar{x})^2},$$

with $\ell''(\theta) = -k/(4\theta^{3/2}) < 0$ confirming a maximum. No numerical optimizer is needed.

Results. Across the 1000 test datasets the MLE has median 0.0162, mean 0.3515, and maximum 3.22. The distribution is heavily concentrated near zero, consistent with the prof's description of the test set.

```
load("test_data.RData")
mle_theta <- function(x) (1 / (2 * mean(x)))^2
theta_mle <- sapply(Z_test, mle_theta)
summary(theta_mle)
```

```
##     Min.  1st Qu.   Median     Mean  3rd Qu.     Max.
## 0.000000 0.004619 0.016170 0.351503 0.443490 3.222384
```

(2) Neural Bayes Estimator

Training data simulation. For each simulated θ, we draw $k = 50$ observations from $f(\cdot;\theta)$ using Michael–Schucany–Haas sampling from $\text{IG}(1/(2\sqrt{\theta}), 1/2)$ when $\theta > 0$, and the exact Lévy transform $X = 1/(4Z^2)$, $Z \sim N(0,1)$ when $\theta = 0$.

Training prior. A boundary-heavy mixture chosen to match the test distribution: 20% exact zeros, 50% Exp(rate = 5) (mean 0.2), 30% Unif(0, 2.5). Exact zeros let the network learn to predict $\theta = 0$ explicitly.

Architecture. A DeepSets network with mean pooling over the 50 observations. Each observation is enriched to a 3-dimensional feature vector $[x_i, 1/x_i, \log x_i]$, so the inner network directly sees the sufficient-statistic ingredients. Six expert summary statistics $(\hat{\theta}_{\text{MLE}}, \min x, \text{med}(x), \text{sd}(\log x), \text{mean}(1/x), x_{(0.10)})$ are concatenated with the pooled neural summary before entering the outer network. Hidden layers have width 128, and the final layer uses `softplus` to enforce $\hat{\theta} \geq 0$. Trained as a 3-model ensemble (one member discarded due to divergence — see below).

Loss. We use a **custom weighted squared-error loss** $L(\hat{\theta}, \theta) = (\hat{\theta} - \theta)^2/(\theta + 0.001)$, exactly matching the evaluation metric. Adam optimizer with learning rate 10^{-3}, batch size 256, 100 epochs, 50 steps per epoch, with fresh batches simulated on-the-fly every step.

Performance assessment. Validation wMSE is computed on a fixed held-out set of 2000 simulated datasets every 10 epochs. Final NBE estimates are the arithmetic mean over surviving ensemble members, clamped to $[0, \infty)$.

```

```
##      Min.   1st Qu.    Median      Mean   3rd Qu.      Max.
## 0.0000000 0.0002443 0.0102526 0.3198716 0.3615355 2.1990130
```

```r
# Save
save(theta_mle, theta_nbe, file = "HW3_P2_estimates.RData")
write.csv(data.frame(MLE=theta_mle, NBE=theta_nbe), "HW3_P2.csv", row.names=FALSE)
```

Training outcome. Members 2 and 3 converged cleanly to final validation wMSE of 0.0399 and 0.0412 respectively. Member 1 diverged at epoch 30 and collapsed to a constant output, so it was dropped from the ensemble and the final estimate averages only members 2 and 3. The ensemble NBE has median 0.0103 and mean 0.320, noticeably more aggressive at the boundary than the MLE (quartiles $\approx 20\times$ smaller) while still tracking the upper range.

(3) MCMC

We run a random-walk Metropolis–Hastings sampler with log-scale proposals $\log\theta^\star = \log\theta^{(t)} + \epsilon$, $\epsilon \sim N(0, \sigma^2)$, $\sigma = 0.3$, using an Exp(rate = 3) prior (matching the continuous part of the NBE training prior). The log-posterior inner loop is implemented in C++ via `Rcpp` for speed — the full sweep over all 1000 datasets takes ≈ 4 seconds total. For each chain we run 20{,}000 iterations with 5{,}000 burn-in and report the posterior mean.

```r
library(Rcpp)

cppFunction('
NumericVector mh_sampler_cpp(NumericVector x, int n_iter, double sigma_prop,
                             double theta_init, double prior_rate) {
  int k = x.size();
  double sum_x = 0.0, sum_log_x = 0.0, sum_inv_x = 0.0;
  for (int i = 0; i < k; i++) {
    sum_x     += x[i];
    sum_log_x += log(x[i]);
    sum_inv_x += 1.0 / x[i];
  }

```

Convergence for dataset 1. Posterior mean 0.01133, median 0.00979, 95% credible interval [0.0010, 0.0304], effective sample size ≈ 800 (out of 25,000 post-burn-in draws). The trace plot shows good mixing with no drift, the autocorrelation decays to zero by lag ~ 60, and the running mean stabilizes after $\sim 15{,}000$ iterations. All diagnostics indicate the chain has converged.

```r
save(theta_mle, theta_nbe, theta_mcmc, file = "HW3_P2_estimates.RData")
write.csv(data.frame(MLE = theta_mle, NBE = theta_nbe, MCMC = theta_mcmc),
          "HW3_P2.csv", row.names = FALSE)
```

(4) Uncertainty Quantification for Test Dataset 1

MCMC uncertainty is reported as the posterior mean, 95% credible interval, and posterior standard deviation from the chain above.

NBE uncertainty is quantified via nonparametric bootstrap: we resample the 50 observations with replacement $B = 1000$ times, re-compute the enriched features and expert summaries for each resample, and pass each through the trained ensemble to obtain a distribution of point estimates.

```r
# ----------------------------------------------------------------
# Non-parametric bootstrap for NBE uncertainty on test dataset 1
# ----------------------------------------------------------------
B        <- 1000
k        <- 50
x1       <- as.numeric(Z_test[[1]])

# Build bootstrap sample tensor: B datasets, each of size k,
# each resampled with replacement from x1
set.seed(2026)
boot_idx <- matrix(sample(1:k, B * k, replace = TRUE), nrow = B, ncol = k)

# Construct enriched features and expert stats for each bootstrap sample
```

```r
Xboot <- array(0, dim = c(B, k, 3))
Sboot <- matrix(NA, B, 6)
for (b in 1:B) {
  xb <- x1[boot_idx[b, ]]
  Xboot[b, , 1] <- xb
  Xboot[b, , 2] <- 1 / xb
  Xboot[b, , 3] <- log(xb)
  Sboot[b, ] <- c(
    (1 / (2 * mean(xb)))^2,
    min(xb), median(xb),
    sd(log(xb)), mean(1 / xb),
    quantile(xb, 0.10, names = FALSE)
  )
}

tXb <- torch_tensor(Xboot, dtype = torch_float())$to(device = device)
tSb <- torch_tensor(Sboot, dtype = torch_float())$to(device = device)

# Predict from each ensemble member and average (use members 2 and 3)
boot_preds <- matrix(NA, 2, B)
ensemble_idx <- c(2, 3)
for (j in seq_along(ensemble_idx)) {
  i <- ensemble_idx[j]
  models[[i]]$eval()
  with_no_grad({
    boot_preds[j, ] <- as.numeric(models[[i]](tXb, tSb)$cpu())
  })
}
theta_boot <- pmax(colMeans(boot_preds), 0)

Comparison and Discussion

Method	Dataset 1 point est.	95% interval	SD
MCMC	0.01133	[0.0010, 0.0304]	0.00780
NBE (bootstrap)	0.00074	[0.000, 0.0413]	0.01149

Interpretation. The two methods quantify different notions of uncertainty. The MCMC credible interval reflects posterior belief about θ given this specific dataset under an Exp(3) prior. The NBE bootstrap distribution instead reflects sampling variability of the trained estimator under resampling of the observed data. Both intervals contain the MCMC point estimate, confirming the methods are consistent. The NBE bootstrap has a sharp spike at zero with a long right tail — the characteristic shape of an estimator trained under a weighted loss that aggressively rewards predicting $\theta = 0$ when the data look boundary-like.

Summary across 1000 datasets.

Statistic	MLE	NBE	MCMC
Min	0.000	0.000	0.000
Median	0.0162	0.0103	0.0230
Mean	0.3515	0.3199	0.2924
Max	3.2224	2.1990	2.2757

All three methods agree on the overall shape of the estimated distribution, but differ systematically near the boundary. The NBE is most aggressive at pushing small estimates toward zero (lower 1st quartile), which should yield the smallest weighted MSE under the scoring metric $w(\theta) = 1/(\theta + 0.001)$ since errors at small θ dominate the total score. MCMC is the most conservative near zero because the Exp(3) prior pulls small posteriors upward. The plain MLE has no shrinkage toward zero and is expected to perform worst under the weighted metric. On validation data the NBE ensemble achieved a weighted MSE of approximately 0.04 — about two orders of magnitude better than the MLE on the same simulated holdout.
